The Balancing Act between Cancer Immunity and Autoimmunity in Response to Immunotherapy

Arabella Young, Zoe Quandt, and Jeffrey A. Bluestone

Abstract

The explosion in novel cancer immunotherapies has resulted in extraordinary clinical successes in the treatment of multiple cancers. Checkpoint inhibitors (CPIs) that target negative regulatory molecules have become standard of care. However, with the growing use of CPIs, alone or in combination with chemotherapy, targeted therapies, or other immune modulators, a significant increase in immune-related adverse events (irAEs) has emerged. The wide-ranging and currently unpredictable spectrum of CPI-induced irAEs can lead to profound pathology and, in some cases, death. Growing evidence indicates that many irAEs are a consequence of a breakdown in self-tolerance, but the influence of genetics, the environment, and the mechanisms involved remains unclear. This review explores key questions in this emerging field, summarizing preclinical and clinical experiences with this new generation of cancer drugs, the growing understanding of the role of the immune response in mediating these toxicities, the relationship of CPI-induced autoimmunity to conventional autoimmune diseases, and insights into the mechanisms of irAE development and treatment.

Immune-Related Adverse Events (irAEs): The Clinical Experience

Cancer immunotherapies, including monoclonal antibodies, oncolytic viruses, and T-cell therapies, have yielded unprecedented clinical success in the treatment of advanced cancers. Immune checkpoint inhibitors (CPIs) antagonizing the negative regulatory molecules cytotoxic T-lymphocyte–associated protein-4 (CTLA-4), programmed death-1 (PD-1), and programmed death-ligand 1 (PD-L1) have been approved by the FDA for a growing number of cancers and, in some cases, are now being utilized as first-line treatments (1). However, with their increasing use, a significant increase in associated immunotoxicities, termed immune-related adverse events (irAEs), has been observed. These irAEs have been reported in nearly every organ system, often leading to profound pathology and, in some cases, death (2–4). Anti–CTLA-4 and anti–PD-1/PD-L1 therapies display distinct patterns of tissue-specific irAEs, indicative of their differential roles in the maintenance of tolerance (5). Overall, the prevalence and severity of irAEs is greater with anti–CTLA-4 treatment than with anti–PD-1/PD-L1 treatments; however, their use in combination exacerbates the frequency of irAEs. Ipilimumab (anti–CTLA-4) preferentially promotes colitis and hypophysitis, whereas anti–PD-1 treatment is associated with higher rates of thyroiditis, and rare, but sometimes life-threatening, cases of pneumonitis and diabetes mellitus (Table 1; refs. 2, 6–8).

Although increasing experience with these therapeutic regimens has improved the diagnosis and monitoring of irAEs in clinical settings, limited mechanistic understanding remains a major obstacle for their clinical management. In some cases, irAEs are recognized as a consequence of an autoinflammatory response, driven by systemic activation of innate immunity and often treated with high-dose steroids and other anti-inflammatory drugs (9). In other cases, the irAEs are more likely autoimmune in nature, with the presence of autoantibodies and, in some cases, documented antigen-specific, memory T-cell responses indicative of adaptive immunity (6, 10–12). These apparent autoimmune conditions raise a number of key questions. (i) Do CPI-induced autoimmune irAEs develop by unmasking underlying conventional autoimmune diseases, or do they represent an alternate process for initiation of autoimmunity? (ii) Are there conventional adaptive immune mechanisms involved, or are immunotherapies altering novel mechanisms of immune tolerance, inducing systemic or tissue-specific immunity? (iii) What are the genetic or environmental triggers that lead to this collateral damage? In this perspective, we will focus on a number of current efforts to answer these questions. A detailed understanding of the interplay between antitumor immunity and irAEs, preclinical and clinical investigations in irAE development, and methods of identifying patients at risk will be highlighted. Defining the mechanistic basis of irAEs induced by individual immune therapies will lead to more precise therapeutic strategies to dampen or prevent irAEs without impeding antitumor immunity.

Profiling Autoimmunity in Preclinical Models

Preclinical studies examining the role of inhibitory checkpoints can play an important role in delineating clinically relevant immune interactions (Fig. 1). Investigation of CTLA-4 and PD-1 blockade revealed that these molecules elicit differential effects on...
T-cell immunity. CTLA-4 predominantly alters CD4+ T-cell activation in the lymph nodes, whereas PD-1 mediates CD8+ T-cell activity in the tissue (5). CTLA-4–deficient mice rapidly succumb to lymphoproliferative disease with severe multiorgan failure (13, 14). In contrast, mice with PD-1–deficiency have more delayed and restricted pathologies, with tissue-specific infiltration in a strain-dependent manner (15, 16). In non-obese diabetic (NOD) mice, genetically susceptible to the development of autoimmune type 1 diabetes (T1D), anti–PD-1 rapidly induces diabetes, whereas anti–CTLA-4 precipitates disease only in neonates (17, 18). Additional immune checkpoints targeted by either gene-knockout or antibody-directed therapies have been shown to abrogate tumor growth, leading to early-phase clinical testing. However, targeting many of these molecules, including inhibitory receptors TIM-3, LAG-3, and TIGIT (reviewed by ref. 19), has also been shown to potentiate autoimmunity in preclinical models, illustrating the range of tolerogenic mechanisms that contribute to control of a self-directed immune response. CPIs may also act on cells other than naïve and effector or memory T cells. For anti–CTLA-4, evidence in mouse models shows that these antagonists alter regulatory T cell (Treg) numbers and function (20, 21). For anti–PD-1/PD-L1 therapy, this remains unclear, but the PD-1 engagement may functionally control CD28 signaling, a critical costimulatory pathway in Tregs, suggesting they influence these cells as well (22, 23).

The potential for improved antitumor immunity through targeting multiple, nonredundant immunomodulatory pathways has led to early-phase clinical trials for a variety of combinatorial strategies. These combination treatments may improve the efficacy of cancer immunotherapy but may also amplify irAEs. Examining gene-targeted mice with multiple immunoregulatory molecule deficiencies may assist in recognizing potential pathologies and mechanisms for organ-specific disruption of tolerance in response to immunotherapy combinations. PD-1 and VISTA dual-knockout C57BL/6 (B6) mice display increased immune infiltration into tissues, whereas CD96 and PD-1 double-deficient mice have minimal impact on immune homeostasis or pathologies (24, 25). Combined loss of PD-1 and LAG-3 results in lethal autoimmunity in mice (26, 27). Despite differential effects on autoimmunity, each molecule in combination with anti–PD-1 enhances antitumor immunity (24, 26, 28). Thus, cotargeting complementary pathways of immune regulation can clearly affect tumor immunity, but the frequency and severity of irAEs remains to be evaluated fully in clinical trials. Although mouse models may suggest an augmentation in the frequency of irAEs in combination studies, clinical efforts may not reflect this. Anti–LAG-3 plus nivolumab (anti–PD-1) demonstrates a similar safety profile to nivolumab alone (29). Nonetheless, animal models provide a valuable tool for interrogation of organ-specific tolerogenic mechanisms maintained by different immunoregulatory molecules.

The study of CPI-induced toxicity has been limited in many clinical settings due to the rarity of specific events and absence of appropriate tissue material. Animal models have been limited to strains such as B6 and BALB/c mice, which are generally resistant to autoimmune sequelae. Thus, the adverse effects of CPIs have benefited from animal studies that have compromised regulatory pathways. CPI treatment of mice, in which Tregs have been transiently depleted to heighten immune cell activation and lower the threshold to overcome immune tolerance, has been used to increase the risk for immunotoxicity (30). Using a short-term Treg depletion strategy, individual antibodies that antagonize inhibitory and agonize stimulatory immune modulators have been compared. As a single agent, both anti–PD-1 antagonism and agonistic anti-CD137 treatment enhance antitumor activity. However, anti-CD137 treatment leads to more severe toxicities than anti–PD-1, consistent with clinical observations, particularly for hepatotoxicity (31). Antibody-mediated neutralization of tumor necrosis factor (TNF)-α reverses anti-CD137–induced irAEs without impeding antitumor immunity (30). These results suggest that animal models not only may be useful in determining irAE risk but may also facilitate development of combinations that can avoid toxicities while maximizing antitumor activity. B6 mice expressing humanized CTLA-4 identified human CTLA-4

monoclonal antibodies with reduced irAEs compared with clinically approved ipilimumab without compromising tumor control (32). Ipilimumab-mediated antitumor immunity in mouse models expressing human CTLA-4 or human Fcγ receptors was attributed to Treg depletion in the tumor (20, 32). Although limited evidence exists for Treg depletion in anti–CTLA-4–treated cancer patients, ipilimumab patients with Fcγ receptor polymorphisms have improved survival outcomes in tumors with...
high mutational burden (20). Further testing of novel immuno-
therapy combinations in these Treg-compromised models will
determine antitumor efficacy versus immunotoxicity in these
autoimmune-prone settings.

Although the manipulation of standard mouse strains has
been useful, developing tumor models in mouse strains prone
to autoimmune and other immune-related toxicities will pro-
vide additional benefits. NOD mice are predisposed to devel-
opring autoimmune manifestations, and multiple genetic loci
that precipitate autoimmunity have been identified (reviewed in
ref. 33). Some insulín-dependent diabetes (Idd) susceptibility
loci prevent anti–PD-1–induced diabetes (34). Autoimmune
mice allow for detailed investigations of target expression
during autoimmune and antitumor immune conditions. PD-
L1 expression is increased with accumulation of target immune
infiltrate in the islets of Langerhans in NOD mice, suggesting
that the PD-1/PD-L1 axis may be critical for disarming auto-
reactive T cells and preventing T1D onset (35). Diabetes in
NOD mice can also be induced months after tolerance induc-
tion using anti–PD-1 and anti–PD-L1 (36). In addition, ectopic
CTLA-4 expression on pituitary gland endocrine cells may be
the direct target of antibody-mediated hypophysitis following
anti–CTLA-4 treatment through activation of complement
(10, 37). Thus, it will be essential to develop tumor models in
autoimmune-prone strains to enable interrogation of the
autoimmune and antitumor immune interface and provide
insights into the clinical manifestations of irAEs, as well as
various genetic and environmental parameters that better
define the human experience (Fig. 1).

Comparing Conventional and
Immunotherapy-Induced Autoimmunity in
Patients

Determining whether irAEs develop similarly to conventional
forms of spontaneous autoimmunity and, therefore, share com-
mon features such as autoantibody presentation, autoreactive
T cells, and underlying genetic risk factors is of great interest. For
conventional T1D, autoreactivity positivity for islet-associated
antigens is present in over 90% of cases at diagnosis (38), but
in CPI-induced diabetes, the same autoantibodies are positive
in fewer than half the cases (39). Similarly, patients with rheuma-
tological irAEs are negative for rheumatoid factor and cyclic
citrullinated protein antibodies and frequently have low or neg-
ative titers for antinuclear antibodies at presentation (40). In
contrast, thyroid antibodies are associated with thyroid irAEs
induced by anti–PD-1 treatment in non-small cell lung cancer
(NSCLC), suggesting that humoral immunity may play a role in
some forms of irAEs (6).

When autoantibodies related to conventional disease are not
present, screening for alternate antibodies may both assist with
defining disease and providing mechanistic insight by identi-
fying functionally significant pathways for irAEs. In patients
receiving intraslesional Bacillus Calmette-Guérin (BCG) and
ipilimumab for melanoma, an increased number of autoanti-
body specificities was found in individuals with severe irAEs
(41). Similarly, interrogation of global antibody profiles prior
to CPI treatment identified toxicity-associated antibody signa-
tures that were heightened in patients who developed severe
irAEs (42). Minimal signature or functional overlap was iden-
tified between different CPI treatment groups, including mono-
therapy versus combination anti–PD-1 and anti–CTLA-4 treat-
ment (42). This finding also highlights the potential variation
in the mechanism by which autoimmune sequelae develop
in response to CPI treatment but should be replicated with
separation of irAEs based on organ pathology rather than
severity alone. Decreased circulating B cells after CPI treatment
 correlate with time to onset and severity of immunotoxicity,
irrespective of site, with cellular changes preceding clinical
manifestation of irAEs (43). However, whether reduced pro-
portions of B cells reflect egress to tissues, differentiation, or
apoptotic programs and the subsequent effect on antibody
production is not known.

Alterations to the T-cell repertoire in response to CPI treat-
ment have been reported to correlate with both therapeutic
response and severity of irAEs. An increased number of expanded
CD8+ T-cell clones in the periphery of prostate cancer
patients receiving ipilimumab correlated with severe irAEs
(44). Another study confirmed that patients who develop irAEs
display increased T-cell diversification in the periphery 2 weeks
after treatment initiation with ipilimumab and GM-CSF (11).
Determining pathogenic antigen recognition versus bystander
expansion of T-cell clones is of major interest and may repre-
sent an opportunity to develop tolerogenic therapies in the
form of antigen-specific Tregs and peptide-based approaches to
be given prophylactically to at-risk individuals. Similarly, the
presence of previously defined autoreactive T cells from sponta-
nous autoimmune disease has not been assessed in CPI-
treated patients developing irAEs.

Major histocompatibility complex (MHC) genes [human leu-
kocyte antigens (HLA)] are known to confer risk to the develop-
ment of many spontaneously occurring autoimmune diseases.
In hypophysitis, HLA markers DQ8 and DR53 are associated
with sporadic, but not anti–CTLA-4, treatment-associated disease (45).
In CPI-induced diabetes, the T1D high-risk HLA allele DR4 is
significantly more prevalent than reported frequencies in US
Caucasians and individuals who develop spontaneous T1D
(39). As the association between individual irAEs and genetic
variation, including HLA type, are discovered, it may become
clinically useful to carry out genetic risk screening prior to choos-
ing an appropriate CPI treatment plan if multiple treatment lines
have similar antitumor efficacy but are disparate for an indivi-
dual’s risk of irAE.

Serum cytokine levels may also provide predictive value and
mechanistic insight for patient susceptibility to CPI-induced
irAEs. Preexisting, circulating IL17 may predict which ipilimu-
mab-treated melanoma patients could develop severe diarrhea
and colitis (46). IL17 plays a critical role in the pathogenesis of
inflammatory immune-mediated diseases, including various
forms of arthritis and bowel diseases. Gastrointestinal irAEs are
the most common co-occurring immunotoxicities in CPI-treated
patients with inflammatory arthritic irAEs (40). Although defin-
ing a correlation between multiple irAEs requires a greater number
of patients, it may suggest a link between IL17-driven pathogen-
esis and the type of autoimmune sequelae that co-occur in
response to CPI treatment, with potential for a targeted approach
to relieve irAEs.

Taken together, these data suggest that for autoimmune irAEs, T
cells and antibodies recognizing autoantigens may, at least in part,
be responsible for immunotherapy-induced pathologies, but in
many cases, display alternate features compared with conven-
tional autoimmune diseases. However, a more complete
interrogation of these immune processes will be necessary in the human setting by initiating dedicated efforts to collect clinical and mechanistic data longitudinally, starting prior to immunotherapy commencement to understand key parameters of disease etiology and mechanistic considerations.

Environmental Influences on irAEs

Growing evidence suggests that an individual’s gut microbiota can alter immune homeostasis and tolerance. Both microbial diversity and abundance may affect the development of immunotoxicity and antitumor immune responses to CPI treatment by altering the immune composition in the tumor and periphery (47–50). In preclinical models, the presence of certain species of Bacteroides and Bacteroides not only potentiates anti–CTLA-4 tumor control, but also reduces the severity of experimental colitis following CTLA-4 blockade (51). Similarly, enrichment of the Bacteroidetes phylum was identified in colitis-free, ipilimumab-treated melanoma patients (49, 52), whereas the Firmicutes phylum was enriched preceding ipilimumab in patients developing colitis (49). Administration of antibiotics, which potently disrupt commensal microbiota, prior to CPI treatment reduces survival benefit for renal cell carcinoma and NSCLC patients (53) and may further highlight an interaction among microbiota, antitumor immunity, and irAEs. Mechanistically, microbial changes may alter immune responses through cross-reactivity and mimicry of endogenous molecules or tumor-derived neoantigens, promotion of metabolic activity, or influencing recruitment, and polarization of inflammatory immune cells. Understanding the impact of the microbiome on the immune response will be essential in enabling the treatment of dysbiosis and to reestablish equilibrium of the protective gut microbiota to limit irAEs. It will also be equally critical to determine the influence of nongastrointestinal microbiota and whether anti–PD-1/PD-L1–driven irAEs are influenced by microbial composition and other environmental factors.

Treatment of irAEs without Impeding Antitumor Immunity

Studies of differential treatment responses based on irAE development have been conflicting, with some reporting improved response in patients who develop irAEs (4, 54) and others that report no difference (3). Investigation of the effect of individual irAEs within different cancer subtypes may provide more clarity. Vitiligo occurs preferentially in melanoma patients, highlighting a crossover between antitumor immunity and autoimmunity, with hypopigmentation correlated to improved outcome to immunotherapy (55). This is likely due to an interaction between self-antigens that persist in the tumor, which also become an immune target in nonmalignant, pigmented cells. The presence of autoimmune sequelae, such as hypophysitis in patients treated with ipilimumab for melanoma (56), thyroid dysfunction following pembrolizumab in NSCLC patients (6), and gastrointestinal irAEs for CPI treatment of advanced malignancy (57) all reveal favorable survival outcomes despite therapeutic intervention and without clear indication for the shared response. Understanding the mechanism by which autoimmunity and tumor immunity provide interactive responses will assist in developing therapeutic interventions to moderate autoimmune irAEs, without impacting the antitumor immune response.

The mainstay of irAE treatment is corticosteroids of varying doses, depending on the severity of the irAE (9, 58). Some high-grade or corticosteroid-refractory irAEs are treated with additional immunosuppressive agents (9, 58). Because corticosteroids act as a systemic immunosuppressive agent through induction of apoptosis of lymphocytes among other mechanisms, it has been theorized that corticosteroids may attenuate the antitumor immune response initiated after CPI treatment. Although multiple studies have suggested that corticosteroids do not worsen overall survival or other cancer outcome measures (3, 4), these studies have not adequately accounted for the possibility that the response benefit from the irAEs was attenuated by the use of corticosteroids or other immunosuppressive agents. In a study of melanoma patients with ipilimumab-induced hypophysitis, patients treated with low-dose steroids, rather than high-dose steroids, had a significantly better melanoma response to ipilimumab with no difference in clinical benefit for treatment of hypophysitis. This study suggests that the high-dose corticosteroids used to treat irAEs may attenuate the improved response that the irAE portends. Additionally, NSCLC patients receiving corticosteroids at baseline experienced an inferior treatment response to PD-1/PD-L1 inhibitors compared with patients not on chronic corticosteroids (59), suggesting that steroid treatment may be detrimental to CPI-induced antitumor responses.

Other immunosuppressive agents used as second- or third-line therapies for specific irAEs include infliximab, vedolizumab, mycophenolate mofetil, cyclophosphamide, IVIg, plasmapheresis, and others (9, 58), with mounting evidence for the safety and efficacy of these medications for treatment of irAEs. Infliximab neutralizes TNFα (57, 60), whereas vedolizumab is a monoclonal antibody against α4β7 integrin, expressed primarily on a subset of CD4+ T cells in the gut (61), allowing for irAE treatment to be relatively gut-specific. Both have been used for the treatment of steroid-refractory enterocolitis, and some experts recommend early use of infliximab (3, 4, 60). Two small studies (57, 60) comparing cancer outcomes of patients with enterocolitis requiring infliximab in addition to high-dose corticosteroids to patients treated with high-dose corticosteroids alone did not identify a survival difference. However, it was suggested that shortened corticosteroid treatment alongside infliximab may reduce infection risk and improve immune recovery.

Organ-specific and systemic immune responses are not just limited to cancer patients receiving CPIs or other immunomodulatory therapeutics. Cancer patients receiving chimeric antigen receptor (CAR) T-cell therapy can also develop cytokine release syndrome, which has some similarities to CPI-induced irAEs and may provide insights into the overall irAE experience. In the CAR T-cell therapy setting, anti–IL-6/IL6 receptor agents are used in many patients prior to use of systemic corticosteroids because the latter may reduce the efficacy of the CAR T-cell therapy (62). The use of IL6 inhibition for CPI-induced irAEs is not common, but case reports of successful prevention and treatment of irAEs with use of IL6 blockade exist (63–65). Evidence for improved antitumor immune responses with IL6 blockade in combination with PD-1 blockade in preclinical mouse models has also been reported (66). As CAR T-cell therapies become more widely used in the cancer setting, including for solid tumors, it is likely that the number and kind of irAEs will increase, indicating a need to develop animal models to better understand and treat these irAEs (67, 68).
Cancer Immunotherapeutic Strategies That Prevent Induction of irAEs

Although improved mechanistic understanding to monitor and treat irAES will enhance clinical management of immunotherapy-treated patients, development of therapeutic strategies that induce tumor-specific immunity without the threat of systemic irAES will provide greatest clinical benefit (Fig. 1). Targeting intratumoral Tregs without peripheral depletion may improve therapeutic specificity. Fc optimization of a depleting anti-CD25 enhanced intratumoral Treg depletion and, when combined with anti–PD-1, augmented tumor eradication (69). However, a reduction in peripheral Tregs remained evident, highlighting a need for identification of markers that define tumor-infiltrating Tregs. Modulating Treg stability may also promote antitumor immunity with increased therapeutic safety. Targeting Treg-derived EZH2 or NRP1, both having high expression in tumor-infiltrating Tregs, bolsters production of proinflammatory cytokines, leading to antitumor immunity without autoimmune consequences (70, 71). Inhibitors of the epigenetic modifier EZH2 are in early-phase clinical trials as anticancer agents, and their impact on immune cell function should be evaluated.

Bispecific antibodies, and alternate antibody-based structures, that target multiple tumor and immune components simultaneously may selectively enhance localized, tumor-targeted immune activity with reduced risk of irAES. In the clinic, reversible autoinflammatory toxicities, but not autoimmunity, have not been observed in some patients when cotargeting T cells by CD3 engagement alongside tumor antigens. Refined marker selection will be critical to ensure their clinical utility. Dual immunomodulators targeting inhibitory PD-1 and LAG-3, or targeting stimulatory OX40 and inhibitory CTLA-4 are entering early-phase clinical testing (72), providing an opportunity to compare their therapeutic safety and efficacy to monoclonal antibody combination treatment. In addition to multitarget antibody approaches, engineered cell therapies may assist in fine-tuning immune cell responses to provide greater therapeutic control. Orthogonalization of ligand and receptor interactions, which retain native receptor signaling but limit negative pleiotropic, off-target effects, may be used for maximizing the potential of adoptive cell therapies and was achieved for the IL2/IL2Rα interaction (73). Selection of the route for therapeutic administration may also alter the onset of irAES. With increasing interest in intratumoral therapies and observed abscopal effects, it will be important to learn if more localized immunotherapies affect irAES.

Concluding Remarks

The presence of irAES is indicative of an inflammatory immune response and is precipitated due to potential cross-reactivity between tumor and self, underlying predisposition to autoimmunity, or collateral damage from cytokine-induced inflammation. Improving our mechanistic understanding of factors that lead to immunotherapy-induced autoimmune pathologies may facilitate identification of biomarkers to predict or monitor onset of disease, enabling clinicians to more accurately treat autoimmune irAES in immunotherapy-treated cancer patients. Knowledge of those cancer patients with higher susceptibility for irAES will provide improved clinical care and heightened monitoring to prevent complications from the development of potentially life-threatening irAES and limit the impact of treatment disruption to an individual’s cancer care. As we improve our understanding of how each CPI treatment disrupts immune tolerance, we may be able to identify mechanisms to direct patients toward their most appropriate treatment type or engineer alternative therapies that control or prevent tissue inflammation without exacerbating tumor growth to provide optimal antitumor immunity with minimal irAES for greatest clinical efficacy and safety.
